Abstract:

The effects of the use of biological glue in the crater that is left after CO2 laser conisation was studied in a series of 32 cases and compared with a previous study carried out using the same technical methods by the same surgeons. The use of biological glue has as its aim to improve capillary haemostasis after conisation; and so increasing the security of leaving these conisation craters in order to improve the chance of normal morphology later. Biological glue has furthermore never given a febrile reaction, nor has it ever increased the likelihood of scar stenosis. Biological glue however is just an extra method of helping normal morphological healing with a good transformation zone and retaining fertility. When conisation is carried most extensively (in particular as far as depth is concerned) and with the use of powerful laser beams, the application of biological glue seem to guarantee most forms of postoperative haemostasis and good healing.
